

MILLIMETER WAVE-RADAR AND METHOD FOR
MANUFACTURING THE SAME

BACKGROUND OF THE INVENTION

The present invention relates to a millimeter wave-radar mounted on automobiles and a method of manufacturing the same.

5 A millimeter wave-radar for automatic guidance and collision avoidance of a vehicle radiates an electromagnetic wave of a millimeter band in a desired direction and receives a reflected wave from objects in front of the radar to detect possible
10 obstacles.

Conventional millimeter wave-radars have a problem that sidelobes of radiated electromagnetic waves are reflected by objects surrounding a radar fixing portion, resulting in unwanted objects also
15 being detected in addition to targeted objects. A conventional countermeasure to deal with this problem involves installing a metal plate or electromagnetic wave absorber on a plane of and around the transmission/reception antenna in an antenna unit so
20 that it protrudes from the antenna surface, in order to reduce sidelobes, as shown in, for example, JP-A-10-126146,

In the conventional technique described above, however, since the metal plate or radio wave
25 absorber mounted around the transmission/reception

13281 U.S. PTO

022404

antennas are separated from a radome enclosing the antennas, the construction and manufacturing process of the radar itself are complex and the metal plate or radio wave absorber is required to have a sufficient
5 strength. This increases the thickness and weight of the absorber itself.

Another problem is that the metal plate or radio wave absorber is often installed, along with a car-mounted radar, on such locations as will be exposed
10 to wind and rain and thus are required to have an improved weatherability.

An object of this invention is to provide a millimeter-wave radar which is light in weight with an excellent weatherability, prevents unwanted reflection
15 of sidelobes and has an excellent detection performance.

SUMMARY OF THE INVENTION

The above problem is solved by a millimeter-wave radar which comprises: an antenna base having a
20 transmission/reception antenna; a housing fixing the antenna base; and at least a radome or a radar cover enclosing the antenna base; wherein the radome or the radar cover is provided with a radio wave absorbing layer.

25 In a millimeter-wave radar comprising an antenna base having a transmission/reception antenna, a housing fixing the antenna base, and a radome enclosing

the antenna base or a radar cover enclosing the radome, it is preferred that a radio wave absorbing layer, whose performance is adjusted according to its position with respect to the transmission/reception antenna, be
5 integrally formed in an inner surface, inner layer or outer surface of the radome and the radar cover through an insert molding or double molding process as a layer having a predetermined angle to a surface of the transmission/reception antenna or as a composite
10 structure made up of the layer having the predetermined angle and a layer having a predetermined angle to a normal of the surface of the transmission/reception antenna.

With this construction, a mutual engagement
15 between the radio wave absorbing layer that blocks the transmission of radio waves and the material of the radome or the radar cover is facilitated. This construction also allows the performance of the radio wave absorbing layer to be adjusted according to its
20 position with respect to the surface of the transmission/reception antenna. As a result, the layer can offer a maximum performance for radio wave absorption with a minimum required thickness of layer, thereby preventing sidelobes of radiated
25 electromagnetic waves from being reflected by objects surrounding a radar fixing portion.

The radio wave absorbing layer is a layer with a greater dielectric loss than that of the

material of the radome or radar cover, or a magnetic loss layer. Among preferred materials with a high dielectric loss are carbon materials (carbon nanotube, carbon microcoil, shungite carbon, carbon black, expanded graphite, carbon fiber, etc.). Examples of preferred magnetic loss layer include hexagonal ferrite and metals. It is also preferred that the radio wave absorbing layer be formed into a mesh of less than $1/4$ of wavelength so that its own weight can be reduced while maintaining the performance for radio wave absorption.

It is preferred that the dielectric constant of the main materials for the radome and the radar cover, which affects the radio wave transmission characteristic, be adjusted in such a manner that the dielectric constant of a portion of the radome and the radar cover corresponding to the side of the transmission/reception antenna is greater than that of a portion corresponding to the front of the antenna. For example, a part of the radome and the radar cover which corresponds to the front of the antenna may use a material that can pass radio waves without any loss (dielectric constant of 3.0 or less; polycarbonate, syndiotactic polystyrene, polypropylene and a combination of these materials as a main ingredient and ABS). A part of the radome and the radar cover which corresponds to the side of the antenna may have a compounding ratio of glass fibers changed to increase

the radio wave loss (to achieve a dielectric constant in excess of 3.0) or use a material with a greater dielectric constant, such as PBT, than that of a portion corresponding to the front of the antenna and
5 have it integrally formed therewith through insert molding or double molding.

This arrangement allows the radio wave transmission characteristic of the radome or radar cover to be adjusted according to its position with
10 respect to the surface of the transmission/reception antenna. This in turn alleviates adverse effects of sidelobes of the radiated electromagnetic waves without degrading the performance for an electromagnetic wave transmission at the front of the antenna.

15 If one or both of the above two constructions are adopted, a millimeter-wave radar can be realized which has a light, inexpensive construction with an excellent weatherability, prevents unwanted reflection of sidelobes, and offers an excellent detection
20 performance.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE EMBODIMENTS

An embodiment of this invention will be described with referring to the accompanying drawings.

25 Fig. 11 shows a front view of a millimeter-wave radar and Fig. 1 is a cross-sectional view of the millimeter-wave radar taken along the line A-A of Fig.

11. The millimeter-wave radar of Fig. 1 comprises a radome 2, an antenna base 3 incorporating transmission and reception antennas, a control circuit 5, an RF module 4, and a housing 6 fixing the antenna base 3 and
5 accommodating the control circuit 5 and the RF module 4. In front of the antenna base 3 is mounted the radome 2 that covers the entire surface of the antenna base and protects it against bouncing pebbles and rain. Depending on circumstances a radar cover 7 may be
10 installed in front of the radome 2 to enclose it. Further, only the radar cover 7 may be used without the radome 2. It is also possible to use a windshield of the car as a radar cover.

Reference numbers 8 and 9 in Fig. 1
15 conceptually represent a main beam and a sidelobe, respectively, of the radiated radio wave from the transmission antenna.

The transmission/reception antenna in this specification means an antenna arrangement that enables
20 radio wave transmission and reception. If a transmission antenna and a reception antenna are separated, this arrangement is included in the transmission/reception antenna of this specification.

In Fig. 1 the radome 2 or radar cover 7 must
25 transmit a radio wave without reflecting or absorbing it. So, a material for these components preferably has a dielectric constant of 3.0 or less in a frequency range of the millimeter wave used. The material also

needs to have good chemical resistance, mechanical strength and machinability and low cost.

[Table 1]

Table 1 Dielectric constants of various materials (for 76.5 GHz)

Material	Dielectric constant
Polycarbonate (PC)	3.0
Syndiotactic polystyrene (SPS)	2.6
Polypropylene (PP)	2.2
ABS resin	2.7

Generally, a car-mounted millimeter wave-radar is installed on a portion exposed to open air (for example, in front of a radiator or on the back of a bumper). As shown in Fig. 1, sidelobes 9 of the radio wave radiated from the transmission antenna pass through sides of the radome (including cases where sidelobes pass through only the side surfaces of the radome, through only the top and bottom surfaces, through only a part of the side surfaces and of the top and bottom surfaces, and through both side surfaces and the top and bottom surfaces) and are reflected by members making up the vehicle body or those outside the vehicle. These reflected waves may reenter into the radome to be received by a reception antenna which may

detect unnecessary objects in addition to the targeted objects.

Fig. 2 is a cross-sectional view of a millimeter-wave radar of this embodiment and Fig. 3 is
5 an enlarged cross-sectional view of the radome.

In the millimeter-wave radar of Fig. 2, layers with a larger dielectric loss than that of the radome 2 or magnetic loss layers are installed on a part of the side surfaces of the radome 2 (including
10 inner surfaces, inner layers or outer surfaces thereof) in the form of radio wave absorbing layers 10, with their surfaces arranged in an optimum relation to the antenna surface, to absorb sidelobes radiated from the transmission antenna thereby reducing unwanted
15 transmission of sidelobes.

More specifically, the radio wave absorbing layers 10 are arranged as shown in Fig. 3 by insert-molding or double-molding only a layer tilted at a predetermined angle of $\theta 1$ to the surface of the
20 transmission/reception antenna or a composite structure made up of the layer tilted at the angle $\theta 1$ and a plurality of layers tilted at an angle $\theta 2$ toward the normal of the antenna base 3.

This construction allows the sidelobe
25 absorbing material to have only the required thickness to absorb sidelobes without having to increase its mechanical strength. Further, since the performance of the sidelobe absorbing material can be adjusted

according to its relative position to the surface of the transmission/reception antenna, the problem of an increased weight can be avoided.

Further, in the millimeter-wave radar of this
5 embodiment, since the sidelobe absorbing material is provided in a part of the radome, it is possible not only to absorb the sidelobes without complicating the construction or manufacturing process of the antenna unit (antenna and its associated members) but also to
10 protect the antenna surface from wind and rain.

Further, since the sidelobe absorbing material (radio wave absorbing layers) is formed integral with the radome, a mutual arrangement of the sidelobe absorbing material and the antenna base can be
15 done easily.

The radio wave absorbing layers 10 may be formed in a mesh of less than $1/4$ of wavelength through which radio wave cannot pass. It is also possible to provide magnetic loss layers 11 on the radar cover, as
20 necessary, to reduce unwanted transmission of reflected wave from surroundings of the radar fixing portion or from road surfaces.

Examples of the layer with a greater dielectric loss than that of the radome include carbon
25 materials (carbon nanotubes, carbon microcoils, shungite carbons, carbon blacks, expanded graphites, carbon fibers, etc.). The magnetic loss layer may preferably use a hexagonal ferrite (an M-type hexagonal

ferrite with a part of Fe replaced with Ti, Mn, Al or the like, such as $\text{BaFe}_{12}\text{O}_{19}$ and $\text{SrFe}_{12}\text{O}_{19}$).

With these arrangements, a millimeter wave-radar can be realized which is lightweight and
5 inexpensive, has an excellent weatherability, prevents unwanted reflection of sidelobes and has an excellent detection performance.

Another embodiment of a millimeter wave-radar is shown in Fig. 4. In Fig. 14, numeral 12 shows a
10 layer with a dielectric constant than that of a portion of radome 2 which corresponds to the front of the transmission/reception antenna, and numeral 13 indicates a layer with a greater dielectric constant than that of a portion of radar cover 7 which
15 corresponds to the front of the antenna. Fig. 5 shows an expanded cross-sectional view of a radome. A portion of the radome 2 or radar cover 7 corresponding to the front of the transmission/reception antenna needs to pass radio waves without reflecting or
20 absorbing them. A portion of the radome corresponding to the side of the transmission/reception antenna preferably has a larger dielectric constant (3.0 or higher) to prevent transmission of radio waves.

Thus, as shown in Fig. 4, at a certain
25 position in the layer 12 of the radome 2 where a line connecting the position and a center of the antenna surface forms 90 degrees with a normal of the antenna surface (i.e., at a position near the side of the

antenna) the dielectric constant is set to more than 3.0, with the dielectric constant of the radome decreasing as the angle to the normal of the antenna surface decreases (i.e., as the position on the radome moves away from the side of the antenna toward the front). This arrangement realizes a radome 2 or radar cover 7 which passes radio waves in front of the antenna but blocks them at the side of the antenna.

For the radome 2 or radar cover 7 to have a greater dielectric constant in portions corresponding to the side of the transmission/reception antenna than in portions corresponding to the front of the antenna, a compounding ratio of glass fibers contained in a material of the radome may be increased progressively toward the side of the antenna, as shown in Fig. 5, or a material with a large dielectric constant of more than 3.0, such as PBT (polybutylene terephthalate), may be insert-molded or double-molded in the radome. It is also possible to insert-mold or double-mold a meshlike carbon material or hexagonal ferrite with the radome, the size of the mesh being less than $1/4$ of wavelength at which radio waves cannot pass through.

A rate of increase of the dielectric constant with respect to the angle to the normal of antenna surface may be set to a quadratic curve characteristic of (1) of Fig. 1, a straight line characteristic (2) of Fig. 5 or a stepwise characteristic (3) of Fig. 5, or a combination of these. While this embodiment has taken

up an example case in which the dielectric constant is changed according to the angle to the normal of antenna surface, it is also possible to change the dielectric constant in a horizontal lateral direction or vertical direction of the radar cover 7 or radome 2, as shown in Fig. 11. Fig. 11 represents a case where it is desired from the mounting position of the radar that the radio waves not be radiated toward the left on the drawing. Normally, the dielectric constant characteristic may be set laterally symmetric.

Fig. 6 shows an embodiment in which a bumper 14 is used as the radar cover. Figs. 7A-7C are cross sectional views of the bumper. As shown in Fig. 7A, the bumper 14 has a recessed portion 18 in its inner wall in which a millimeter-wave radar 1 is mounted from inside the bumper 14. The millimeter-wave radar 1 may be screwed to, press-fitted to or bonded to the bumper 14. It may also be fixed by screws after insertion into the recessed portion 18. When the radar is fixed, a radar axis is adjusted at the same time.

The inner wall of the bumper 14 is fitted with a radio wave attenuation layer or radio wave absorbing layer 15 whose dielectric constant is large at a portion near the side of the antenna surface of the millimeter-wave radar 1 (dielectric constant: more than 3.0) and decreases as a point of interest on the layer moves away from the antenna surface (dielectric constant: less than 3.0).

More specifically, this may be achieved by progressively increasing a compounding ratio of glass fibers or the like in such a manner that the dielectric constant of a portion of the layer corresponding to the side of the antenna is larger than that of a portion of the layer corresponding to the front of the antenna. Another method involves insert-molding or double-molding a material having a dielectric constant of more than 3.0 or integrally forming a meshlike carbon material and hexagonal ferrite in the bumper inner wall through insert molding or double molding, the mesh size being less than $1/4$ of wavelength at which the radio wave cannot pass through. The connection between the millimeter wave-radar 1 and the vehicle is accomplished through a connector 16a at an end of a harness led out from the radar body as shown in Figs. 7A and 7B or through a connector 16b provided on the millimeter wave-radar 1 as shown in Fig. 7C.

Next, an example method of manufacturing a radome 2 such as shown in Fig. 2 or Fig. 4 will be described with referring to Figs. 8A-8C to Fig. 10.

Figs. 8A-8C show one example method of manufacturing the radome 2. First, as shown in Fig. 8A, the radome 2 is formed by a generally available method such as injection molding. The radome 2 is formed with a recessed portion 21 at a position where the radio wave attenuation layer or radio wave absorbing layer is to be arranged.

Next, as shown in Fig. 8B, the radio wave attenuation layer or radio wave absorbing layer 10, 11 is formed in the recessed portion 21 of the radome 2 by arranging glass fibers or PBT (polybutylene terephthalate) with a dielectric constant of more than 3.0, or by forming a carbon material of a greater dielectric loss than the radome 2 or a hexagonal ferrite into a mesh of $1/4$ of wavelength at which the radio waves cannot pass through.

10 The radio wave attenuation layer or radio wave absorbing layer 10, 11 may also be formed by inserting or pasting the above-mentioned material prepared separately into the recessed portion 21 or through injection molding. The only requirement during
15 this process is to set the dielectric constant higher in a portion of the radome corresponding to the side of the antenna than in a portion corresponding to the front of the antenna, as shown in Fig. 4 or Fig. 5.

 The radio wave attenuation layer may be
20 formed by using a material with a dielectric constant of more than 3.0 or a combination of this material and a radome 2 material. A method of changing the dielectric constant may involve increasing the thickness of the layer toward the side of the antenna
25 or increasing a compounding ratio of glass fibers or a material with a dielectric constant of more than 3.0.

As shown in Fig. 8C, an opening of the recessed portion 21, in which the radio wave

attenuation layer or radio wave absorbing layer 10, 11
is installed, is closed. This may be accomplished by
inserting and bonding a separate member 22 or by
filling the recessed portion 21 with the same material
5 as the radome 2 to enclose the radio wave attenuation
layer or radio wave absorbing layer 10, 11.

It is noted that, even in the construction in
which the radio wave attenuation layer or radio wave
absorbing layer 10, 11 is exposed on the inner side of
10 the radome, as shown in Fig. 8B, the desired effect of
this invention can be produced. But since the interior
of the radome 2 is a space into which outer air enters
and is subjected to humidity and temperature changes,
it is preferred as shown in Fig. 8C that the radio wave
15 attenuation layer or radio wave absorbing layer 10, 11
not be exposed, in order to minimize degradation of the
layers and their characteristics.

In the embodiment shown in Figs. 8A-8C, we
have described the radome fabrication method which,
20 after the entire radome 2 has been formed, double-molds
it with a material having a dielectric constant of more
than 3.0 to form the radio wave attenuation layer or
radio wave absorbing layer. We have also described
another radome fabrication method which pastes a
25 separately formed radio wave attenuation layer or radio
wave absorbing layer to the inner surface of the
radome. It is also possible, as shown in Figs. 9A and
9B, to prepare a mold 102 that defines a shape of the

inner wall of the radome 2 and arrange glass fibers or a material with a dielectric constant of more than 3.0 on the mold 102 for molding the entire radome 2.

Alternatively, the material placed on the mold may be a
5 carbon material with a greater dielectric loss than the radome 2 or hexagonal ferrite, both formed into a mesh of $1/4$ of wavelength at which radio waves cannot pass through.

Figs. 10A-10C show an example case in which
10 the radome 2 is fabricated by injection molding.

First, as shown in Fig. 10A, a material that passes radio waves radiated from the millimeter wave-radar 1 is injected into a mold 101 to form a front part of the radome 2.

15 Next, as shown in Figs. 10B and 10C, a side portion of the radome 2 is formed by either switching the material being injected to glass fibers or a material with a dielectric constant of more than 3.0, such as PBT (polybutylene terephthalate), or mixing
20 these materials in the same material as the front part of the radome 2 and injecting them, thus locally changing the electromagnetic characteristic of the radome 2 to provide the side portion of the radome with a radio wave attenuation characteristic.

25 To make the dielectric constant higher in the side portion of the radome than in the portion corresponding to the front of the transmission/reception antenna, as shown in Fig. 4, the side portion

of the radome needs to be formed by increasing a
compounding ratio of glass fibers or a material with a
dielectric constant of higher than 3.0, such as PBT,
from the front portion toward the side portion of the
5 radome (in Figs. 10A-10C, from left to right).

Further, various characteristics shown in Fig. 5 can be
realized by changing, according to the location in the
radome 2, the amount being mixed or used of the glass
fibers or the material having a dielectric constant in
10 excess of 3.0.

This arrangement makes it more difficult for
the radio waves to pass through the radome as the area
of interest in the radome approaches the side of the
transmission/reception antenna, thus alleviating
15 adverse effects of the sidelobes. Since the radome or
radar cover is a one-piece molded component, the mutual
adjustment between the radome and the antenna base is
made easy.

The radome adopting one or more of the above
20 embodiments is combined with the housing 6, which
accommodates the separately manufactured antenna base 3
and the control circuit 5, and they are fixed together
as by screws, thus completing a millimeter-wave radar.
With this arrangement, a millimeter-wave radar can be
25 realized which has a light, inexpensive construction
with an excellent weatherability, allows easy
positioning of the radio wave absorbing layers with
respect to the antenna base without complicating the

structure or manufacturing process of the antenna base, prevents unwanted reflection of sidelobes, and offers an excellent detection performance.

5 This invention can provide a millimeter wave-
radar which has a light, inexpensive construction with an excellent weatherability, prevents unwanted reflection of sidelobes, and offers an excellent detection performance.

10 It should be further understood by those skilled in the art that although the foregoing description has been made on embodiments of the invention, the invention is not limited thereto and various changes and modifications may be made without departing from the spirit of the invention and the
15 scope of the appended claims.
